# News Authorship Identification with Deep Learning

---

**Liyu Zhou Huafei Wang**

Electrical Engineering Aeronautics & Astronautics  
Stanford University

lyzhou@stanford.edu huafei@stanford.edu

## Abstract

Authorship identification identifies the most possible author from a group of candidate authors for academic articles, news, emails and forum messages. It can be applied to find the original author of an uncited article, to detect plagiarism and to classify spam / non-spam messages. In this project, we tackled this classification task in author level, article level, sentence level and word level with various deep and non-deep classification algorithms and GloVe word vectors are used as the pre-trained word vectors. Among all the algorithms, sentence-level Recurrent Neural Network (RNN) achieves the best performance since it captures the context information as well as word / sentence sequence information from the training dataset.

## 1 Introduction

Authorship identification (authorship attribution) determines the likelihood of a piece of writing to be produced by a particular author by examining other writings by that author. Author Identification study is useful to identify the most plausible authors and to find evidences to support the conclusion. It can be applied in many tasks such as authorship characterization, detecting plagiarism, cybercriminal analysis and classifying spam / non-spam messages. This is a highly interdisciplinary area as it takes advantage of machine learning, information retrieval, and natural language processing.

Authorship identification problem has been studied in the last few decades with various of methods and techniques. Most previous studies such as [1,2,3,4] used stylometric analysis techniques for analyzing and attributing authorship of literary texts. Stylistic features are used in the stylometric analysis which include attributes or writing-style markers that are the most effective discriminators of authorship. The vast array of stylistic features includes lexical, syntactic, structural, content-specific, and idiosyncratic style markers [1].

Over 1,000 different features have been used in previous authorship analysis research, with no consensus on a best set of style markers. This could be attributable to certain feature categories being more effective at capturing style variations in different contexts. This necessitates the use of larger feature sets comprised of several categories of features (e.g., punctuation, word-length distributions, etc.) spanning various feature groups (i.e., lexical, syntactic, etc.) [1].

As a result, the performance of authorship identification tasks depends highly on the chosen features and the quality of these features. Therefore reliable and efficient techniques are needed to extract these features.

For learning, we have both supervised learning and unsupervised learning at our disposal. Supervised learning are those that require author-class labels for classification, while unsupervised techniques make classification with no prior knowledge of author classes. In this paper, we only focus on the supervised learning paradigm.

054 Supervised learning methods used in previous studies include regularized least squares, support  
055 vector machine (SVM), decision tree, feed-forward neural network and etc. on various datasets  
056 (Twitter, RCV1, PAN 2012 and etc.). The accuracy varies significantly when different approaches  
057 and datasets are used from low 20s to high 90s.

058 This paper researches the news authorship identification problem by exploring different machine  
059 learning algorithms on different levels  
060

- 061 • Article-level linguistic features represented by average word length and etc. with non-deep  
062 machine learning algorithms (e.g. support vector machine).
- 063 • Word-level features represented by word vectors with Global Vectors for Word Representa-  
064 tion (GloVe) with different classifiers (e.g. nearest neighbor).
- 065 • Recurrent Neural Network (RNN) with pre-trained GloVe word vectors. A sentence vector  
066 is generated as the input in each step. The number of steps is the number of sentences in  
067 the article.  
068

069 GloVe pre-trained word vectors are used since GloVe captures the word context information (such  
070 as word similarity). We mainly focus on Recurrent Neural Network (RNN) on GloVe word vectors  
071 since we believe that RNN can also capture the word / sentence sequence information which can  
072 help us to better classify the authorship of articles. The experiment results confirm this assumption.

073 We focus on news articles since news articles provide not only stylometry features as in other types  
074 of texts, but also context information since journalists tend to focus on a narrow range of topics and  
075 thus context can also be leveraged for the identification purpose.  
076

## 077 **2 Approach**

### 078 **2.1 Dataset**

079 A subset of the Reuters RCV1 news article dataset is used to develop our multi-level machine learn-  
080 ing algorithms. The dataset contains 5000 news articles for 50 different journalism authors (100 texts  
081 per author) and pre-splits the dataset 50-50 for training and testing. The dataset is obtained from the  
082 Center for Machine Learning and Intelligent Systems hosted by the University of California, Irvine.  
083  
084  
085

### 086 **2.2 Baseline**

087 High-level linguistic features of articles are used as attributes in our baseline model. The following  
088 stylometry features are used: Average Word Length, Average Sentence Length, Hapax Legomenon  
089 Ratio (fraction of unique words).  
090

091 Traditional machine learning methods including Support Vector Machines, Naive Bayes, Random  
092 Forest and etc. are implemented utilizing the above features.  
093

### 094 **2.3 GloVe**

095 GloVe is an unsupervised learning algorithm for obtaining vector representations for words. Train-  
096 ing is performed on aggregated global word-word co-occurrence statistics from a corpus, and the  
097 resulting representations showcase interesting linear substructures of the word vector space [5].  
098

099 In this project, GloVe pre-trained word vectors are used to encode the training articles and find the  
100 most representative vector that can represent the author. Then the test articles are encoded using  
101 the same GloVe word vectors to obtain the most representative vector that can represent the article.  
102 Different GloVe word vector dimensions are used to evaluate their influence on the performance of  
103 the algorithm. F1 Score is used for evaluation.  
104

### 105 **2.4 Recurrent Neural Network**

106 Recurrent Neural Network (RNN) is also implemented to tackle this task. GloVe pre-trained word  
107 vectors are used to encode each word in the article. The standard model - sigmoid hidden layer and

108 softmax projection layer are used, which are as follows.  
109  
110

$$111 \quad e^{(t)} = x^{(t)}L \quad (1)$$

$$112 \quad h^{(t)} = \text{sigmoid} \left( h^{(t-1)}H + e^{(t)}I + b_1 \right) \quad (2)$$

$$113 \quad \hat{y}^{(t)} = \text{softmax} \left( h^{(t)}U + b_2 \right) \quad (3)$$

114  
115  
116  
117  
118  
119 The input vector in each step is a pre-trained constant vector which can represent a word, a sentence,  
120 a paragraph or even an article, which will be discussed in detail in the next section.  
121

122 A more complex RNN model – LSTM / GRU with forget gate, input gate and output gate is also  
123 implemented in our model. This approach is adopted since we believe that some words in the  
124 article are not representative to the author so they may pose no effect or even negative effect on the  
125 prediction results while some words are truly indicative of the author and they should be assigned  
126 higher weights.

127 Since the size of our dataset is moderate, dropout is applied to the input and output of the RNN  
128 model in order to mitigate the undesirable overfitting.  
129

130  
131

## 132 **3 Experiment**

133  
134

### 135 **3.1 Baseline**

136 Several machine learning methods including Support Vector Machines, Naive Bayes, Random  
137 Forest and using the stylometry features are implemented. The best accuracy is achieved by Gradient  
138 Boosting Classifier with an **12.24%** accuracy.  
139

140 The low accuracy is expected as only 3 high level summary features are used. As discussed in the  
141 Introduction, over 1000 different stylometry features are used in previous studies in order to have a  
142 satisfactory classification performance.  
143

144 In addition, word, sentence and paragraph contexts as well as sequences that may contain author  
145 writing style and pattern information are discarded during the summarization and feature extraction  
146 process.  
147

148 This preliminary result serves as a baseline for this project.  
149

150  
151

### 152 **3.2 GloVe**

153 The F1 Score and confusion matrix visualizations with the Nearest Neighbor Classifier ( $L_2$  Dis-  
154 tance) are shown below. We can observe that the classification with GloVe greatly outperforms the  
155 baseline methods because of the different context information associated with each author that is  
156 able to be extracted and aggregated from their articles using GloVe.  
157

158 It can also be observed that the higher the word dimension is, the higher the  $F_1$  score the result  
159 has. The highest  $F_1$  score of the Nearest Neighbor Classifier comes with GloVe word vectors with  
160 dimension 300, which is around **0.46**. This is reasonable since higher dimension word vector can  
161 generally capture more context information of a word.

### 3.3 RNN

The following two approaches of data input are implemented for RNN

- Word level approach. A single word vector is fed into RNN in one step. So the number of steps of RNN is the number of words in each article. Since there are typically a large number of words in each article, there will be too many steps, which has caused the gradient vanishing problem. The result we have obtained is poor, with the highest  $F_1$  score around **0.2**. Besides, since each article has a different length, different models for each article have to be built separately. As a result, the training is undesirably slow. Paddings have been added to the articles to make them have the same length. But unfortunately, since the length of articles covers a wide range - from 200 to 1500, adding paddings does not enhance the performance significantly.
- Sentence level approach. The mean vector of each sentence is calculated and fed into the RNN model at each step. This approach also captures the word / sentence sequence information since the RNN process is recurrent. Because that the average number of sentences of all articles is around 15-20, this model does not suffer from the gradient valishing problem, so it significantly outperforms the word level approach. The highest  $F_1$  score we have obtained is around **0.6**. In addition, the training is relatively fast compared with the word level RNN approach.

Confusion matrix visualizations of sentence level RNN with different GloVe word vector dimensions are shown below.

216

244  
245  
246  
247

We can see from the figures that the sentence level RNN Classifier with GloVe word vectors of dimension 300 has the best performance, with the  $F_1$  score around **0.6**.

248

The training loss and validation loss values of sentence level RNN are shown below

264

265

266

267

268

269

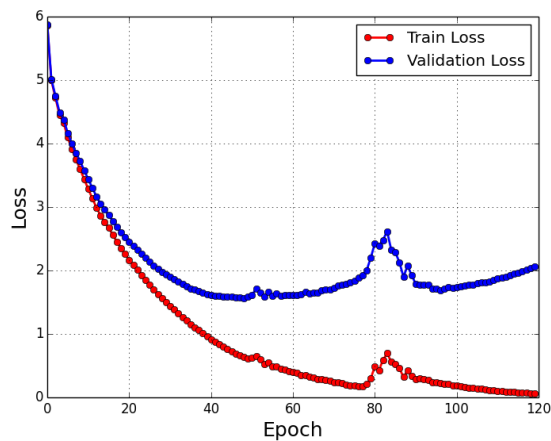

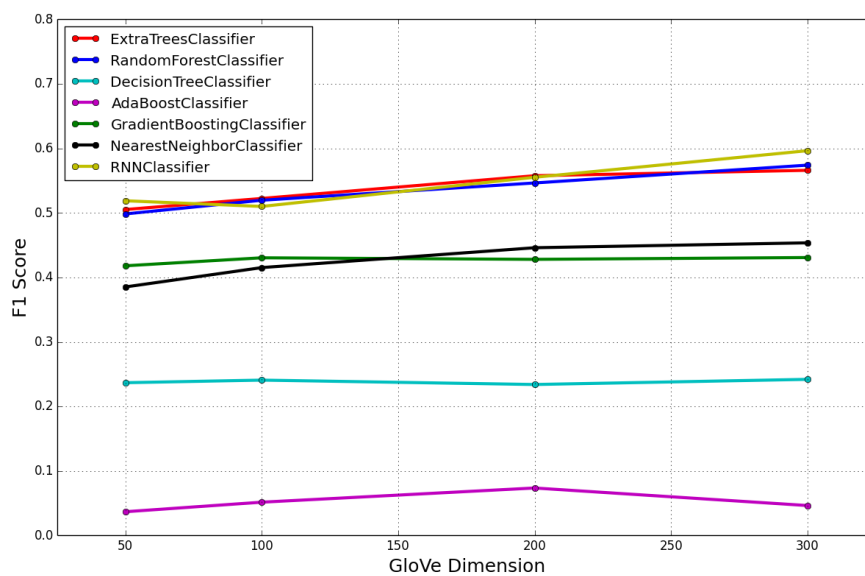

Figure 9: Loss History for RNN

It can be observed from the figure that despite some small spikes in the curve, the training loss value keeps decreasing. The validation loss value drops to a minimum value and then starts to increase.

270 Typically we can get the best model for prediction (test accuracy) when the validation loss reaches  
 271 the minimum value. Usually the training algorithm will terminate at the first small spike of the  
 272 validation loss curve. But in order to show the full trend of the training and validation loss, more  
 273 epoches have been run in our attempt.  
 274

### 275 3.4 Comparing with Other Machine Learning Algorithms

276  
 277 Several other machine learning algorithms that are typically powerful in various of prediction tasks  
 278 are also implemented. These algorithms include Random Forest Classifier, Extra Tree Classifier,  
 279 Decision Tree Classifier, AdaBoost Classifier, and Gradient Boosting Classifier. For these methods,  
 280 GloVe word vectors are used to encode the articles and calculate the mean vector for each article and  
 281 predictions are based on the calculated mean vector. The comparison results of different machine  
 282 learning algorithms are shown below.  
 283  
 284

302  
303  
304 Figure 10: Different ML Methods with GloVe

## 305 4 Conclusion

306  
 307 We have presented various methods for authorship identification task with a focus on the Recurrent  
 308 Neural Network approach. Stylometry features lose information and performs poorly in the authorship  
 309 identification task. GloVe captures context information for different authors and performs relatively  
 310 better. RNN, in addition to capturing context information, also captures word / sentence  
 311 sequence information and has the best performance with a **0.6**  $F_1$  score.  
 312  
 313

314 However, the RNN approach does not show significant advantage over other machine learning meth-  
 315 ods. For future work, we can attempt to improve the performance of RNN to truly unleash its power.  
 316 Some strategies are as follows.

- 317 • Use a larger dataset. This is extremely important since our model is already suffering from  
 318 overfitting problem and a larger dataset can help us remedy the situation.
- 319 • Currently, we are using GloVe pre-trained vectors as our constant word vectors in our  
 320 model. We can let the GloVe pre-trained vectors be the initial values for the word embed-  
 321 ding variables and update them in each RNN step.
- 322 • For large enough dataset, we can use neural network to train our own word vectors instead  
 323 of using the pre-trained GloVe word vectors.
